

The gain collapses at the extreme of dependence and peaks in the severe band

Admission Barthel category against what each group gained, raw and corrected for the ceiling.

a. Mean points gained during the stay

b. The same groups, corrected for the ceiling

Panel b divides each group's total gain by its total available margin, $\Sigma \Delta BI \div \Sigma (100 - \text{admission BI})$. The fall on the right of panel a is the ceiling, not a clinical finding: a patient admitted at 80 cannot gain more than 20 points. Panel b removes that constraint and the peak in the severe band survives it — so the rise on the left is real and the fall on the right is not. Independent patients on admission (BI 100, n=4) are left out of both panels: their margin is zero, so the ratio is undefined. Floor effect and profound deficit are both plausible for the BI <20 group; these data cannot separate them.
